Religion and cooperative attitudes: Evidence from Indonesia

Abstract

Using the latest round of the Indonesian Family Life Survey (IFLS), I investigate the correlations between religion and cooperative attitudes such as altruism, trust, and tolerance. I investigate these associations for different religions in Indonesia, a country where Islam is the majority religion but recognizes other world religions such as Catholicism, Protestantism, Hinduism, Buddhism, as well as Confucianism. Meanwhile, the attitudes studied here naturally fall under what Guiso et al. (2011) called "civic capital", i.e., "those persistent and shared beliefs and values that help a group overcome the free rider problem in the pursuit of socially valuable activities".

I find that: (i) religiosity is associated with a higher willingness to help and trust of individuals within one's own community, but not with the (generalized) trust of strangers; (ii) however, religiosity is associated with more religious discrimination; (iii) interestingly, but consistent with the social psychology literature, religiosity is also associated with greater ethnic discrimination; and (iv) among Muslims and, to a much lesser extent, Protestants, religiosity is negatively associated with tolerance. The evidence, therefore, suggests that religion may be linked to "parochial altruism" (Bernhard et al., 2006; Choi and Bowles, 2007), which is altruism towards members of one's own group combined with hostility towards members of the out-groups. The link appears to be strongest for adherents of the country's majority religion.

Keywords: religion, cooperation, parochial altruism, Indonesia
JEL Codes: D71, D72, Z12

*I would like to thank James Ng, Jeffrey Nugent, Geert Ridder, Tirta Susilo, and Teguh Yudo Wicaksono for their valuable inputs. In particular, I would like to thank my advisor, John Strauss, for his guidance. All remaining errors are mine.

1 Introduction

For believers, religion is both a source of values and social identity. Since economic interactions are affected by an individual's priors, including his or her social identity, religion and religious beliefs could influence economic outcomes (Weber, 1905; Akerlof and Kranton, 2000; McCleary and Barro, 2006). There is an increasing interest among economists in exploring the causal link between religion and economic outcomes. Guiso et al. (2006) suggest three steps to establish such a link: First, one needs to establish the direct impact of culture on expectations and preferences. The next step is to show that these beliefs and preferences have an impact on economic outcomes. The final challenge is to identify and establish the direction of causality between culture and outcomes.

This study primarily contributes to this first step. I examine the correlations between religion and cooperative attitudes such as altruism, trust, and tolerance.[1] In particular, I investigate this link for different religions in a society where Islam is the majority religion. To this end, I employ the Indonesian Family Life Survey (IFLS) data to examine how religion and religious intensity correlate with cooperative attitudes in Indonesia, a country with a Muslim majority but acknowledges four other main world religions (Catholicism, Protestantism, Hinduism and Buddhism) as well as Confucianism.

There is ample evidence demonstrating how these cooperative attitudes contribute to economic outcomes. Generalized trust can improve institutional quality and reduce transaction costs, and its impacts have been shown using case studies (Putnam et al., 1993) as well as quantitative methods using cross-country data (Knack and Keefer, 1997; La Porta et al., 1997) and household-level data (Narayan and Pritchett, 1999; Maluccio et al., 2000; Carter and Castillo, 2011). Carter and Castillo (2011) provided empirical evidence of the important role of altruistic sharing norms in improving household well-being in South African communities.

Meanwhile, economic historians have documented how intolerance could stunt economic outcomes by slowing down technological progress. Landes (1998), for instance, argued that religious intolerance was responsible for scientific regress in many (Catholic) European countries. Similarly, Chaney (2008) has argued that religious tolerance and diversity contributed to scientific progress in medieval Muslim societies by facilitating inter-religious

[1] All three attitudes studied here naturally fall under what Guiso et al. (2011) called "civic capital", i.e., "those persistent and shared beliefs and values that help a group overcome the free rider problem in the pursuit of socially valuable activities".

debates. However, once Islam became the *de facto* majority religion, intolerance prevailed which eventually led to the decline of intellectual enterprise in these societies

To my knowledge, this is the first country study that looks at the link between religiosity for different world religions and cooperative attitudes. A similar study previous to this is by Mujani (2004). Mujani examines the correlates of the different types of Islamic religious practices on aspects of social capital among Indonesian Muslims. In this study, I am interested in investigating the relationship between religion and cooperative attitudes for different religions – not just Islam. Moreover, with the rich IFLS dataset, I can check for and address the potential sources of biases much more rigorously.

I find that: (i) religiosity is associated with a higher willingness to help and trust of individuals within one's own community, but not with the (generalized) trust of strangers; (ii) however, religiosity is associated with more religious discrimination; (iii) interestingly, but consistent with the social psychology literature, religiosity is also associated with greater ethnic discrimination; and (iv) among Muslims and, to a much lesser extent, Protestants, religiosity is negatively associated with tolerance. The evidence, therefore, suggests that religion may be linked to "parochial altruism" (Bernhard et al., 2006; Choi and Bowles, 2007), which is altruism towards members of one's own group combined with hostility towards members of the out-groups. This link appears to be strongest among adherents of the country's majority religion, to wit, Islam. It also qualifies claims that there is a benign relationship between religiosity and inter-group cooperation in Indonesia (e.g., Mujani, 2004, p. 329).

In the next section, I begin with a brief review of the literature on religion and beliefs and attitudes. It reviews what is known about the link between religiosity and attitudes from social psychology as well as economic studies based on observational data and experiments. Section 3 then elaborates the empirical strategy to identify the link between religion and civic capital. It elaborates the data used as well as the measurements for both the dependent and independent variables. In Section 4, I describe my findings. In addition to reporting the pooled results, I report the differential effects of religiosity on attitudes by gender and age groups. I also conduct a preliminary robustness check of these results to potential biases from interviewer effects. Section 5 concludes.

2 Religion and cooperative norms

Does religion increase altruism, trust, and tolerance? Since all religions teach benevolence, we would expect that it does. Moreover, we would also expect that altruism, trust, and tolerance to be increasing with the religiosity of the individual. Existing evidence, however, does not fully corroborate these expectations.

On altruism, sociological surveys based on self reports often provide evidence that people who attend religious services and pray more are more likely to contribute to charity. Social psychology studies, however, call these findings into question. Batson et al. (1993) compared between studies that used self-reports measures and those using behavioral ones to examine the link between helpfulness (or altruism) and religious involvement. They found that the positive associations often found using the former measures disappeared when behavioral measures were used. Similarly, using economic experiments, Anderson et al. (2010) did not find religious involvement to be a significant predictor of contributions in public goods games. Further evidence suggests that the positive findings based on self-reports may have been driven by stronger reputational concerns, instead of actual willingness to help, among the religious (Batson et al., 1993; Norenzayan and Shariff, 2008).

Meanwhile, there is also mixed evidence on the link between religiosity and trust. Analyses of observational data provides the evidence for the link between religiosity and trust. Using the generalized trust question from the World Value Survey (WVS) data for 66 countries, Guiso et al. (2003) found that religious people trust others more than the non-religious (although not compared to atheists). Among the religious, trust toward others is positively correlated with current religious participation, but not by whether a person is brought up religiously. Using a similar question on generalized trust, Mujani (2004) found that participation in the various Islamic rituals was correlated with more interpersonal trust.

However, the evidence from economic experiments is more mixed. As a behavioral measure of trust, experimenters often use the game developed by Berg et al. (1995). In this "trust game", a proposer (or the "truster") is given an initial endowment and can pass some of his endowment to a responder (or a "trustee"). The amount passed is multiplied by three (or an amount greater than one) and is given to the trustee. The trustee then can choose the amount the she would like to give back to the truster. The amount passed by the truster is can be thought of as a measure of the individual's trust of the anonymous partner.

Anderson et al. (2010) did not find the link between the intensity of religious participation and trusting behavior among American subjects when the trust game is played anonymously. However, when participants are informed of the partner's religiosity, Tan and Vogel (2008) found an effect of religiosity among German subjects. They find that the religious are trusted more, particularly by the religious others. Moreover, the religious trustees are also found to be more trustworthy.

The one relationship in which both observational and experimental evidence align is that between religiosity and tolerance. Results based on observational as well as behavioral evidence since Allport and Kramer (1946) first found the positive association between religious affiliation and racial prejudice are strongly in favor of finding a positive link between religiosity and intolerance (Batson et al., 1993; Hall et al., 2010; Guiso et al., 2003). More recently, experimental evidence using priming of religious concepts provide further evidence that when one's religious identity is made salient, there is greater intolerance towards members of the out-group – both in terms of religion and ethnicity (McCauley, 2009; Johnson et al., 2010; Parra, 2011).[2]

The next question is whether the specifics of each religion matters for cooperative behavior. Benjamin et al. (2010) used priming to examine the impact of the salience of religious identities among Catholics, Protestants, Jews, and non-believers. After receiving religious priming, subjects were asked to play experimental games to measure their contributions to the public goods and dictator games. Among Catholics, religious priming decreased public good contributions and expectations of other's contributions, while among Protestants, it increased contributions. However, religious identity did not affect generosity in the dictator game.

With respect to trust, the cross-country analysis of Guiso et al. (2003) found that participation in religious services increases trust only among Christians. Among the Christian denominations, Putnam et al. (1993) has argued that because of its hierarchical structure, Catholicism tend to breed less interpersonal trust than Protestantism. Observational analyses using cross-country data found support for this conjecture, although this difference was smaller among younger Christians (La Porta et al., 1997; Guiso et al., 2003). [3] However, such a difference is not found in the analysis using United States data (Alesina and La Ferrara, 2002).

[2]Moreover, McCauley (2009) also found that the effects of salient religious identities on inter-group discrimination are stronger than those of tribal ones.

[3]Guiso et al. (2003) show that Catholics born after the Second Vatican Council are more trusting and tolerant than their older cohorts, even though their moral values did not significantly differ from older Catholics.

Meanwhile, the link between religion and intolerance are present across all religious denominations, with a notable except of Buddhists, who are on average more tolerant than non-religious people. The least intolerant towards immigrants and other races were Hindus and Muslims, followed by Jews, Catholics and Protestants (Guiso et al., 2003).

The link between religion and cooperative attitudes at the individual level may also be affected by aggregate level variables. In particular, religious diversity at the community level may have an influence on the level of individual trust. If individuals exhibit homophily – i.e., the tendency of individuals to identify with others who are similar – then one would expect to see greater interpersonal trust in more homogeneous society (Alesina and La Ferrara, 2002).[4] On the other hand, as suggested by Allport (1954), contacts with people who are different will break down stereotypes and reduce prejudice. Hence, diversity could potentially reduce discriminative trust and intolerance.

3 Empirical strategy

At the individual level, the three main variables of interest are religiosity, religion, and the interactions between the two variables. Meanwhile, the community-level variables of interest are two religious diversity variables, to wit, the religious fractionalization and religious polarization variables. Since the religion variables are only available in the latest wave of the IFLS, the analysis here will be cross-sectional. For all of these variables, I address the issue of the endogeneity in two ways. First, I include the standard control variables (e.g., demographic and expenditure variables) and other variables that may affect outcomes, based on the literature, at various aggregations.

Second, I also include fixed effects at different levels of aggregation. For religiosity and the religiosity$\times$religion interactions, I implement both community and household fixed effects. The household fixed effects potentially remove more unobservables than community fixed effects; however, at the same time, it removes the effects of religiosity that have been "institutionalized" in the household. In the case of religiosity, about two-thirds of the households in the sample have homogeneous religiosity.[5] In the results sec-

[4] In the case of the United States, Alesina and La Ferrara (2000) and Alesina and La Ferrara (2002) found a negative correlation between trust and ethnic fragmentation in a community.

[5] Out of 12,680 household, 8,387 households have homogeneous religiosity. Out of 8,387 households with homogeneous religiosity, 2,943 households have a single member. In terms of the number of individuals, however, only about 44% of individuals in the sample live

tion, I present the results from both models. Similarly, for the analysis of inter-religion differences, given that in almost half of the districts in the sample, respondents have homogeneous religion, I implement the province fixed effects.[6] Meanwhile, I implement province and district fixed effects to analyze the link between community-level diversity and cooperative attitude.

Despite efforts to address these sources of endogeneities, it is likely that these estimates are not completely free of potential latent variables. For instance, household fixed effects may have been able to absorb some of the differences that are inherent to a family (such as genetic differences); however, they cannot eliminate intra-household unobservables such as personality differences. Given this limitation, the following results should be interpreted as correlations – albeit, precisely estimated ones. In addition, words like "impact", "affect" or "influence" are to be seen as exposition tools, and refer to correlations instead of causation. At the same time, these findings correspond very well with what we know about the effect of religion on cooperative behaviors, including those based on experimental evidence.

All estimates in the main paper are made using OLS.[7] For province and district fixed effects models, standard errors are clustered at the community level. For the community fixed effects model, standard errors are clustered at the household, while for the household fixed effects model, standard errors are robust.

3.1 Data

The main dataset for the analysis is the Indonesian Family Life Survey (IFLS), a longitudinal, socio-economic household survey based on a sample representing 83% of the Indonesian population living in 13 out of 26 provinces in 1993. The survey collects a rich set of information on households and the communities they live in, as well as the facilities that are available to them. Until now, there are four full-sample waves of the survey (IFLS1-IFLS4), conducted in 1993, 1997, 2000, and late 2007.[8] In subse-

in these homogeneous-religiosity households.

[6] Out of 233 districts in the sample, 112 districts have homogeneous religion. In terms of the number individuals, about 33.8% of individuals live in the sample's homogeneous-religion districts.

[7] As a robustness check (not reported), I have also implemented the ordered logit fixed effects model of Baetschmann et al. (2011) for most of the models. Overall, the results from the two estimations are similar.

[8] In 1998, an additional survey interviewing 25% of the sample, known as IFLS2+, was conducted to measure the impact of the economic crisis.

quent waves, IFLS follows the same individuals and households, as well as their split-offs.

For this analysis, I use the fourth wave of the IFLS (IFLS4). IFLS4 added new sets of questionnaire modules that were not available in previous survey waves. These new modules include questions on religion (and religiosity), general trust, community trust, and tolerance. These questions will be the basis of the main analysis in this paper. IFLS4 will also be the main source of data for all other individual and household-level variables. In total, IFLS4 interviewed 29,060 adults in 12,688 households.

In addition to IFLS, I use the 2000 Indonesian Population Census to construct the community-level religious diversity variable. The census collected information on individual religion. In principle, it has 100% coverage of the population on all indicators, although in practice, numbers for some areas were estimated due to political issues in post-transition Indonesia (Suryadinata et al., 2003, p. xxiv).

Finally, I also use the 2007 National Socio-economic Survey (*Susenas*) data to construct the regional inequality measure. Susenas is a repeated cross-section survey that collected household information, including household expenditure and household size, and is representative at the district level. Since 1989, the survey is fielded annually. Using these variables, I constructed the district-level gini coefficient for per-capita expenditure as a proxy of regional inequality. I use the 2007 Susenas, which is the closest year prior to the implementation of IFLS4.

3.2 Measures of altruism, trust and tolerance

IFLS4 contains a number of questions that measure different aspects of cooperative norms and attitudes. In one set of questions, respondents were asked to rate on a four-point Likert-type scale – from "strongly disagree" to "strongly agree" – the following statements:

(i) "I am willing to help people in this village if they need it";

(ii) "In this village I have to be alert or someone is likely to take advantage of me";

(iii) "I would be willing to leave my children with my neighbors for a few hours if I cannot bring my children with along";

(iv) I would be willing to ask my neighbors to look after my house if I leave for a few days".

Table 1: Summary statistics for the trust and tolerance variables

	Mean	Std. dev.	Median	IQR	Min	Max
Community altruism and trust						
Willingness to help	3.15	0.38	3	0	1	4
Must be cautious	3.04	0.45	3	0	1	4
Trust neighbor to watch [...]						
children	2.68	0.57	3	1	1	4
house	2.87	0.46	3	0	1	4
Village is [...]						
generally safe	3.07	0.37	3	0	1	4
safe at night	2.99	0.38	3	0	1	4
Trust						
Trust [...] to return lost wallet						
neighbors	3.03	0.94	3	1	1	4
police	2.81	0.99	3	2	1	4
strangers	1.52	0.78	1	1	1	4
Discrimination						
Trust [...] more						
coreligionist	2.80	0.58	3	1	1	4
coethnic	2.65	0.58	3	1	1	4
Tolerance						
Tolerate non-coreligionist to live in [...]						
village.	2.80	0.54	3	0	1	4
neighborhood.	2.75	0.58	3	0	1	4
house.	2.43	0.73	3	1	1	4
Tolerate non-coreligionist to [...]						
marry a relative.	1.77	0.81	2	1	1	4
build house of worship	2.26	0.79	2	1	1	4

In addition, respondents were asked to assess how safe their villages were; and how safe it was to walk around at night. This set of questions can be interpreted as measures of community norms. Responses to (i) can be interpreted as a measure of local helpfulness or altruism, while responses to (ii), (iii), (iv), and the safety questions can be interpreted as measures of the level of community trust.

In another set of questions, respondents were asked to imagine a scenario where they lost a wallet or a purse containing Rp. 200,000 (or approximately US$20) along with an identity card. Respondents were then asked to assess how likely they would get the wallet back with the money intact if it were found by: (i) someone who lives close by; (ii) a policeman; and (iii) a stranger. Respondents can respond on a 4-scale measure from "very unlikely" to "very likely". Their answers provide us with a measure of trust – more specifically, as argued by Guiso et al. (2011), they are assessments of the likelihood of being cheated by different types of anonymous "opponents".

Respondents were also asked to rate on a four-point Likert-type scale the following statements about trust of people of the same ethnicity and religion: "Taking into account the diversity of ethnicities (religions) in the village, I trust people with the same ethnicity (religions) as mine more". I use answers to these questions as measures of in-group trust and ethno-religious discrimination.

Finally, as measures of religious tolerance, I use a set of questions regarding respondent attitudes towards others of a different religion (or non-coreligionists). In particular, IFLS4 asked whether respondents object to having non-coreligionists live in their village, neighborhood, or house. It also asked whether respondents would object if one of their relatives was going to marry a non-coreligionist and if people of a different religion were to build a house of worship. In all these questions, respondents can respond on a 4-scale measure, from "no objection at all" to "not acceptable".

Table 1 presents the summary statistics for these outcome variables. In general, respondents report a high level of community altruism and trust, while at the same time, maintain a high level of caution. The combination of a high level of caution with a high level of community trust appears paradoxical. However, a principal-agent model of Breuer and McDermott (2011) suggests a mechanism of which we can obtain this relationship at the societal level: All else constant, an increase in caution indirectly increases the incentives to be trustworthy while at the same time directly reduces trust. They show that the net effect of the direct and indirect channels from

caution to societal trust is always positive.[9] For the different types of trust, respondents are also trusting of their neighbors and, to a lesser extent, the police. However, their trust of strangers – which is often seen as the type of trust that matters most in facilitating economic outcomes (Glaeser et al., 2000; Guiso et al., 2011) – is much lower.

Meanwhile, based on the averages of the tolerance measures, we can rank the issues captured by these measures from the most to the least contentious. Interfaith marriage is the most contentious, followed by the issue of allowing non-coreligionists to build a place of worship. Relative to these two issues, respondents are much more tolerant about allowing non-coreligionists live in the same village or neighborhood, but not so much in the same house.

Table 2: Summary statistics for the regressors

	Mean	Std. dev.	Median	IQR	Min	Max
Individual-level variables						
Religiosity	2.82	0.56	3	0	1	4
Male	0.48	0.50	0	1	0	1
Age	36.87	15.62	34	22	13	100
Years of education	7.40	4.02	9	3	0	18
Received corelgn edu.	0.21	0.41	0	0	0	1
Received non-corelgn edu.	0.02	0.16	0	0	0	1
Married	0.70	0.46	1	1	0	1
Risk aversion	2.38	1.27	3	0	-1	3
Patience	1.48	0.93	1	1	0	4
Number of prior migrations	0.59	1.12	0	1	0	14
Household-level variables						
Crime	0.06	0.23	0	0	0	1
Violent crime	0.00	0.05	0	0	0	1
Majority religion (village)	0.94	0.23	1	0	0	1
Monthly PCE	437373	684939	286109	327101	0	5.83E+007
Village-level variables						
Urban	0.44	0.50	0	1	0	1
Religious fractionalization	0.10	0.14	0.03	0.14	0	0.71
Religious polarization	0.18	0.23	0.07	0.26	0	0.94
District-level variables						
District PCE gini	0.26	0.05	0.26	0.06	0.17	0.38

[9] I find positive correlations between the community-level averages of caution and willingness to help as well as caution and trust of strangers. However, I do not find a correlation between caution and trust of neighbors.

3.3 Measures of religion and religiosity

Our analysis focuses on examining how religion and religious intensity correlate with social and civic capital in Indonesia. In IFLS4, each respondent was asked about his or her religion and can choose between Islam, Catholicism, Protestantism, Hindu, Buddhism, and Confucianism For this analysis, we drop the 24 observations who answered Confucianism. Each respondent was also asked to evaluate his or her own religiosity out of a 4-scale measure – "not religious", "somewhat religious", "religious" and "very religious". These two variables and their interactions will be our main regressors of interest. Table 3 presents the distribution of religiosity overall and for each religion.

Table 3: Distribution of religiosity

	Not religious	Somewhat religious	Religious	Very religious	Num. of obs.
All religions	0.03	0.19	0.73	0.06	28973
Islam	0.03	0.19	0.73	0.05	25890
Catholic	0.03	0.15	0.72	0.09	447
Protestant	0.02	0.15	0.76	0.07	1157
Hindu	0.01	0.05	0.77	0.17	1392
Buddhist	0	0.21	0.70	0.09	87

The religiosity question in IFLS is a self-assessment question; it is therefore useful to examine how answers to these questions relate to observed behavior. For adherents of each religion, IFLS4 asked a pair of questions on an individual's religious practices. Muslims were asked how many times they prayed every day and whether they observed the *halal* food requirement. Christians were asked how often did they pray or read the bible and whether they actively participated in activities such as religious fellowships. Meanwhile Buddhists and Hindus were asked whether they meditated in the temple and whether they observed certain religion-related diets. I use these information to validate respondents' self-assessments of their religiosity.

Table 4 presents the share of individuals that follow a particular religious practice for a given level of religiosity and for each religion. The pattern suggests correlations between self-assesment of one's religiosity and his or her adherence to religious practices across different religions. For Muslims, the more religious a person, the more likely that he or she follows (and go beyond) the mandatory number of prayers of five times a day. However, there

Table 4: Share of practicing individuals for a given religiosity

	Not religious	Somewhat religious	Religious	Very religious	Refused to answer
Muslim					
How many times do you pray each day?

Num. of obs.		18	61	8	1

$^*\chi^2$ calculations exclude respondents who refuse to answer the religiosity question.

does not seem to be much variation with respect to keeping the *halal* diet across different religious intensities, except among the non-religious muslims. Similarly among Christians, the more religious tend to pray more frequently during the day. In addition, they are also more likely to participate actively in religious activities such as prayer fellowships. Meanwhile, more religious Hindus are more likely to frequent temples daily, and are more likely to maintain follow the no beef/red meat dietary restrictions. Similarly, more religious Buddhists are more likely to pray in the temple daily and be a vegetarian.

Table 5: Share participating in religious activities in the village[†]

	Not religious	Somewhat religious	Religious	Very religious
All religions	0.29	0.41	0.61	0.70
Islam	0.28	0.40	0.59	0.66
Catholic	0.27	0.57	0.80	0.76
Protestant	0.45	0.62	0.76	0.88
Hindu	0.67	0.66	0.79	0.82
Buddhist	-	0.00	0.26	0.57

[†] Responses to whether respondents participate in any religious activity held in the village in the past 12 months.

To further validate this measure, I also consider a question from IFLS's community participation module – which is a module that is separate from the religion module. In the community participation module, respondents were asked whether they knew of a particular activity in the village, and if they do so, whether they participated. Included in the list of activities inquired is a religious activity. Table 5 presents a summary on responses for different levels of religiosity. Participation is monotonically increasing in religiosity except between the non-religious and somewhat religious Hindus, and religious and very religious Catholics.

3.4 Measures of religious diversity

Local religious diversity might also have an effect on cooperative norms. To capture diversity, I consider two diversity measures, namely fractionalization and polarization indices. The fractionalization index used here is calculated using the formula used to construct the ethno-linguistic fractionalization (ELF) index, namely:

$$RF_i = 1 - \sum_{r}^{N} s_{ir}^2 \tag{1}$$

where RF is the religious fractionalization index, i indexes the community, and r indexes the religion. s_{ir} is the share of religion r in community i. This index describes the likelihood that a random draw of two individuals from community i results with two individuals with different religions. It can take a value between 0 and 1, with 0 denoting a perfectly homogeneous community.

One criticism of the fractionalization index, particularly in connection to conflict studies, is that it is atheoretical and fails to reflect the underlying model of inter-group tensions. Reynal-Querol (2002) argue that polarization indices are more appropriate to capture the potential link from diversity to social conflicts. I therefore also separately estimate models with the religious polarization index suggested by Reynal-Querol (2002), i.e.:

$$RQ_i = 1 - \sum_{r}^{N} (0.5 - s_{ir})^2 s_{ir}/0.25 \tag{2}$$

where RQ_i is the Reynal-Querol polarization index for community i, and like before, s_{ir} is the share of religion r in community i. The index is 1 when the community is "perfectly" polarized with two religious groups, each comprising half of the community and is zero if the community is perfectly homogeneous.

I use the 2000 population census to construct both indices at the village level. However, IFLS only provides village location identifiers for the original 311 villages; for respondents who moved outside of the original villages, IFLS only provides the subdistrict location identifiers. Hence, for those who moved out of the original villages (or the "movers"), I constructed the diversity variables by first constructing diversity indices for villages in all IFLS subdistricts. I then take averages of the village-level diversity variables for each subdistrict and assign them to the movers.[10]

3.5 Control variables

I implement the same set of control variables across outcomes, which is summarized in Table 2. In all models, I include the standard individual

[10]Due to issues with matching IFLS with the 2000 Census, I am not able to assign 157 individuals with community-diversity indices.

characteristics such as sex, age, married status, and years of education. To address potential non-linear effects of age, I include linear splines with knot points at at 25, 45, and 65 years old. Similarly for education, I also introduce linear splines for years of education with knot points at 6 and 12 years of education.[11]

Meanwhile, many religion-based education institutions often function as a source of oblique or horizontal socialization of religious values and beliefs. The values transmitted through these institutions in the past may affect cooperative attitudes at present. To capture this, I employ data on each individuals' education history. IFLS contains information on the types of institution managing the schools attended by the respondents, including whether it is a religion-based – to wit, Catholic, Protestant, or Buddhist, but not Hindu – institution. With this information, I construct an indicator of whether the respondent receives an education from an institution of her religion (or a "coreligion education") or a religion-based institution that is not of her religion (or a "non-coreligion education").[12]

The decision to cooperate can be a risky act. I therefore include the individual's measure of risk aversion. IFLS elicits risk aversion by asking respondents to choose payoffs with different risk levels. However, risk aversion is elicited using without real payoffs. There are some concerns about potential biases from this approach; however, the experience from the Mexican Family Life Survey suggests that such biases may not have been so severe (Strauss et al., 2009).

Moreover, Glaeser et al. (2002) has an interesting model linking social capital investment with individual mobility and discount factor. For the former, IFLS records the number of prior migrations of each adult. Meanwhile, to measure the latter, IFLS employs a set of questions, asking respondents to choose different payoffs that give returns at different times from today. Similarly, the discount factor is elicited without real payoffs. Both of these variables are included as regressors.

At the household level, I include the per-capita log expenditure with a level spline at the median and whether the a member of the household was recently a victim of a crime. At the community level, I include an indicator of whether the community is an urban or rural one. Finally, at the district level, I include the district level gini coefficient in 2007, calculated using the

[11] The coefficients for the all of the linear splines represent the slopes of the interval.

[12] In order to obtain this information, I need to use the panel nature of the dataset and link with the education history from the first wave of IFLS (IFLS1). However, IFLS1 conflated Buddhists and Protestant schools into a single category. In these cases, I assume that the respondent is attending a Protestant-managed school.

Susenas dataset.

4 Results

4.1 Demographic and other variables

Before examining how religion is correlated with cooperative attitudes, let us first look at the link between the other (non religion-related) regressors and outcomes. Tables 6 and 7 present regression results for community altruism and trust, while Tables 8 and 9 present results for different types of trust, including discriminative trust. Finally, Tables 10 and 11 present results for religious tolerance. All of the above tables are estimates with community and household fixed effects. However, the exposition will mainly focus on the community fixed effects model, which in this case is the preferred specification.

4.1.1 Gender

Men exhibit a greater willingness to help neighbors while at the same time are more cautious. Men also are more trusting of their neighbors, as shown by the positive and significant coefficients on their willingness to trust neighbors to watch their children and their house (Table 6), as well as the coefficient on their assessment on whether they expect their neighbors to return their missing wallet (Table 8). Men are also more likely to perceive the village to be safe than women.

Moreover, men are also more trusting of strangers and exhibit less discriminative trust with regards to ethnicity and religion. Consistent with the finding on discriminative trust, men are also generally more tolerant. There is an exception, however: Men are not more tolerant – although they are neither less tolerant – than women in allowing non-coreligionists build their house of worship in the village than women . Men are also less trusting of the police.[13] These effects are robust to the different fixed effects specifications.

The findings on interpersonal trust broadly align with what is known about gender differences in social preference. In their paper on trust using the United States data, Alesina and La Ferrara (2002) find that women exhibit less generalized trust. Similarly, in their survey paper of gender differences in the experimental literature, Croson and Gneezy (2009) find

[13] Guiso et al. (2003) also found negative, albeit insignificant, coefficient of being a male and trust towards the police.

that in trust games, women tend to trust less and that their decisions to trust are more sensitive to social distance.

4.1.2 Age

With only a cross-section dataset, we cannot disentangle between age and cohort effects. Hence, the analysis below will confound both effects. Helpfulness of neighbors does not differ across different ages, and only declines slightly by age in the oldest age bracket ($\geq$ 65 years old). The willingness to trust neighbors to watch one's children or house when away is increasing with age up until around the early middle age. However, the assessment of the neighbor's trustworthiness (i.e., whether they would return one's lost wallet) does not vary by age. The assessment of the trustworthiness of a police officer decreases with age when one is very young (before 25 years old) and then, increases with age up until around the early middle age.

Up to early middle age, trust toward strangers increases with age. However, discriminative trust towards those of one's religious group – but not ethnic group – also increases with age from adulthood up until early middle age. Consistent with this result, religious tolerance is also declining with age from adulthood up to early middle age – except for tolerance regarding non-coreligionists' house of worship, which is not correlated with age beyond adulthood. Meanwhile, tolerance with regards to inter-faith marriage increases during the late middle age.

4.1.3 Education

There is a non-linear effect of education on cooperative attitudes. The willingness to help increases with years of education up until 12 years of education, and the slope is steeper between 6 and 12 years of education. An additional year of education between 6 and 12 years also increases caution and reduces the willingness to entrust neighbors with one's children or house when away, and is also associated with a lower assessment of village safety. At the same time, an additional year of education up until 12 years of education is also associated with a higher assessment of the trustworthiness of one's neighbors, with a steeper slope for those with between 6 and 12 years of education.[14]

[14] Although this, and similar results below showing that the sign for the coefficients on trust toward neighbors to be the same as those on caution, appear to be counterintuitive, they are not unreasonable. A principal-agent model by Breuer and McDermott (2011) show that although caution can directly reduce trust, it also can indirectly increase trust by increasing trustworthiness. Their model finds the net-effect of caution towards trust

Trust of the police increases with an additional year of education, but only up to 12 years of education. However, in this case, the slope is steeper in the first six years. Moreover, an additional year of education beyond high school is negatively associated with the trust of the police.

An additional year of education also facilitates more generalized trust of strangers, but only among those with more than elementary education. The slope of the correlation between an additional year of education and generalized trust is steeper for years of education beyond high school. An additional year of education during middle and high school is also associated with less discriminative trust with respect to both religion and ethnicity. It is also positively correlated with all tolerance measures, except for that regarding interfaith marriage – the most contentious issue when we compare the averages across the different tolerant measures (see Table 1). In fact, an additional year of education is associated with more intolerance with respect to interfaith marriage. In contrast, an additional year of education up to the end of elementary school is positively associated with tolerance only for the least contentious issues of allowing non-coreligionists live in the same village or neighborhood. An additional year of elementary school education is negatively associated with tolerance with respect to allowing non-coreligionists build a house of worship or marry a relative. There is no additional tolerance benefit from an additional year of education beyond high school.

4.1.4 Risk and time preferences

Individual risk preferences do not appear to be correlated with cooperative attitudes within the in-groups. Instead, they are mainly correlated with some of the measures of cooperative attitudes with the out-groups. Risk aversion is negatively correlated with the trust of strangers and the three most contentious issues of tolerance, to wit, interfaith marriages, non-coreligionists' house of worship, and allowing non-coreligionists to live in the house. One result that is counterintuitive is the positive correlation between risk aversion and tolerance regarding allowing non-coreligionists to live in the neighborhood; however, this correlation is not robust to the household fixed-effects specification.

Meanwhile, results from Glaeser et al.'s (2002) static model suggest that (local) social capital should increase with the individual discount factor. We therefore expect the discount factor to be positively correlated with

to be positive.

community trust and altruism. However, our results here provide a mixed support for this prediction. Under the community fixed effects, the discount factors is correlated with some of the outcome variables, but many of these relationships are not robust to the household fixed-effects specification. Only three relationships are robust in both specifications: A higher discount factor is associated with more willingness to help and a more cautious attitude. It is also negatively correlated with discriminative trust with regards to ethnicity.

4.1.5 Mobility

Glaeser et al. (2002) also predict that local social capital would decline with mobility. In addition, migrations expose individuals to people from different backgrounds may ameliorate prejudice.[15] The results suggest that some support of the former, and a more robust support for the latter hypothesis. Mobility is associated with a more cautious attitude and less trust of neighbors under the community fixed effects, but not the household fixed-effects specification.[16] It is also associated with more trust of strangers, less discriminative trust and more tolerance across all tolerance measures except with regard to the interfaith marriage of a relative. The associations with respect to cooperative attitudes toward the out-groups are robust under both fixed-effects specifications for most of the indicators.

4.1.6 Household welfare

Higher welfare is associated with less in-group bias and does not appear to be associated with community trust and altruism. Among households with more-than-median per-capita expenditure (PCE), higher welfare is correlated with a less willingness to entrust one's house to the neighbor. Better welfare is also associated with less discriminative trust with respect to ethnicity and religion. It is also associated with greater tolerance of having non-coreligionists in the village. For those with above-median PCE, log PCE is also positively correlated with more tolerance of having non-coreligionists in the neighborhood and allowing them to build their house of worship. However, it is not correlated with tolerance on allowing non-coreligionists stay in the house and for those with below-median PCE, it is negatively correlated with tolerance regarding inter-faith marriage.

[15] On the other hand, the causality may go the other way: Less prejudiced individuals are more willing to migrate.

[16] However, since individuals move together with members of their households, including the household fixed effects may have removed too much of the variation in the case of mobility.

4.2 Religiosity and religion-based education institution

Religiosity is positively correlated with cooperative attitudes involving members of the community and the in-groups, but not of the out-groups. Religiosity is positively correlated with helpfulness and willingness to trust neighbors with one's children and property (Table 6) as well as a higher assessment of the neighbor's trustworthiness (Table 8). More religious people also perceive the village to be safer.

At the same time, it is also positively correlated with religion-based and ethnic-based discriminative attitudes. It is uncorrelated with the trust of strangers and negatively correlated with *all* measures of tolerance (Tables 10 and 11). Religiosity is also positively associated with the trust toward the police. The signs and significance of all coefficients on religiosity are robust to both community and household fixed effects, although they are smaller in the latter specification.[17]

Education from an institution with particular religious orientation has an impact on cooperative attitudes toward the out-groups. Having coreligion and non-coreligion education has no impact on local altruism or non-discriminative trust. However, having a coreligion education is associated with more trust of coreligionists, and less religious tolerance across all measures under the community fixed effects specification. In contrast, having been educated by a non-coreligion religious institution reduces religion-based discriminative attitude, and increases tolerance across all of the measures, except the least contentious one (i.e., allowing non-coreligionists to live in the same village). This latter result may be interpreted as support for Allport's (1954) contact hypothesis.

4.3 Does the religion matter?

In addition to religiosity, I also explore whether different religions affect cooperative attitudes differently. Finding differential estimates for different religions is suggestive of the importance of the different religions on behavior. However, I agree with the interpretation suggested by Guiso et al. (2003) that the inter-religion differences may not necessarily reflect the true meaning of the teachings. Instead, it may very well reflect how the teachings

[17] Upon examination, we find that 88.2% and 2.02% of individuals who live in households with homogeneous religiosity reported themselves to be, respectively, "religious" and "very religious", compared to 53.8% and 10.9% in the heterogeneous-religiosity households. The lower magnitudes of the coefficients in the household fixed effects therefore arrive in part from removing the effects from the more religious individuals in these homogeneous-religiosity households.

have evolved to become the cultural traditions of adherents of these religions in Indonesia. In this sense, we examine how these religio-cultural traditions affect civic capital in Indonesia.

I approach the question in two stages. In the following, I will look at the average effects of religion. That is, controlling for religiosity (and other control variables), I examine whether the different religions of the individuals affect the intercepts of the various cooperative attitudes differently. Then, in Section 4.3.3, I examine how different religions differentially affect the link between religiosity and cooperative attitudes.

Before I begin with the analysis of inter-religion differences, some caveats on the results are in order. First, as is the case in many multiethnic, multireligion countries, ethnicity and religion are not easily separable in Indonesia. In this particular context, two adherents of two of the religions are ethnically homogeneous: 88% of Hindus are Balinese and 81% of Buddhists in the sample are of Chinese descent. In addition, 86% of Hindus live in the province of Bali. Hence, the analysis cannot rule out confounding ethnicity effects. Second, the sample for Buddhists are very small – there are only 88 Buddhist respondents in the sample – and therefore, the estimates of its coefficients have low power.

4.3.1 Inter-religion differences in cooperative attitudes

Tables 12 to 17 present the results of the province fixed effects estimations. In these regressions, Islam is the omitted religion for the interaction variables. Overall, there appears to be very little inter-religion differences in terms of community and non-discriminative cooperative attitudes. However, there are significant inter-religion differences in terms of discriminative trust and tolerance and these differences are mainly between Muslims, who are the majority in the country, and the rest.

With respect to cooperative attitudes in the community, Christians are less willing to help their neighbors compared to adherents of other religions. Among the Christians, Protestants are less willing than Catholics. Meanwhile, Buddhists are less willing to trust their neighbors to watch their children or property. Hindus are less likely to assess their village to be generally safe, and Catholics are more likely to find their village safe to walk at night. There is no inter-religion difference on the three non-discriminative trust measures.

However, in terms of discriminative trust, Muslims trust their coreligionists more compared to adherents of other religions. They are also more intolerant in all tolerant measures. Meanwhile, Catholics have the least discrim-

inative trust with regards to religion, followed by Buddhists, Protestants, and Hindus. Buddhists and Catholics also have less ethnic bias. Catholics and Buddhists are among the most tolerant across all tolerance measures, except (in the case of Buddhists) in allowing non-coreligionists live in their house. Catholics are also more tolerant than Protestants across all measures.

4.3.2 The role of the majority status

In their cross-country analysis, Guiso et al. (2003) found that adherents of the majority religion tend to be more intolerant. The question is whether this phenomenon exists within countries. To explore this question, I include a variable that indicates whether the respondent is adhering to the majority religion in the village. In this sample, no Catholic and only 6 Buddhists live in a village where their religion is the majority religion. Our discussion will therefore focus only on the other three religions.

The right half of Tables 12 to 17 present the religion results with the majority status variables included. Protestants with a majority status in the village have greater willingness to help neighbors, assess the village to be safer and are also more trusting of neighbors compared to those who are not. Majority Protestants also, on average, reported a greater willingness to help neighbors and more trust of neighbors compared to others in the sample. Meanwhile, Muslims are less trusting of the police when they are in the majority, and majority Muslims are also less trusting of the police than majority Hindus or Protestants.

Majority status in the village does not appear to significantly affect discriminative trust. It is positively associated with more coethnic bias for Protestants at 10% significance. However, majority status is significantly correlated with tolerance, except for the least contentious issue of allowing non-coreligionists to live in the village. Among Muslims, the magnitude is largest on the issue of allowing non-coreligionists to build a house of worship, followed by that for the interfaith marriage of a relative. In comparison, majority Protestants and Hindus are more tolerant than majority Muslims on the issue of interfaith marriage and Protestants are more tolerant on allowing non-coreligionists' build their house of worship.

4.3.3 Religiosity, religious education, and religion

In Section 4.3.1, I look at how the different religions correlate with cooperative attitudes controlling for religiosity. However, as explained before, due to the homogeneity of religion for respondents living in almost half of

the districts in the sample, the estimations of inter-religion differences are made using the province fixed effects. A preferred specification to detect the inter-religion differences would be to have fixed effects at a lower level of aggregation. In addition, that model assumes that answers to the self-reported religiosity question are comparable across different religions. However, it is plausible that different religions interpret the meaning of religiosity differently.[18]

To address those problems, I take a different approach to identify the impact of religion on cooperative attitude. Instead of controlling for religiosity, I examine the coefficients for the interactions between religion and religiosity in the household fixed-effects model. Assuming that people rarely switch religion in Indonesia, religion can be treated as an intergenerationally transmitted attribute that is somewhat exogenous. However, for a given religion, people can choose the level of religiosity. Religiosity is, therefore, likely to be endogenous to attitudes. Suppose a personality trait, say sociability, affects both tolerance and religiosity. That is, sociable people tend to be more tolerant and, at the same time, choose a low level of religiosity if he is "transmitted" an intolerant religion. Under this interpretation, a more positive religiosity coefficient for a particular religion (compared to others) indicates that within this religion, the more tolerant tends to be more committed.

The results are shown in in Tables 18 to 23. The link between religiosity and community cooperative attitudes is weaker among Protestants compared to other believers. For willingness to help neighbors, the slope on the religiosity coefficient is more negative for Protestants compared to those of other religions. In other words, as Protestants become more religious, their reported willingness to help does not increase as much as that of adherents of other religions. Similarly, increased religiosity also does not improve the assessments of the safety in the village and trust of neighbors as much for Protestants as for adherents of other religions. In contrast, the strength of the links between religiosity and the willingness to help neighbors and the assessments of village safety for Hindus are more positive compared to those for other believers.

With regards to discriminative trust, the link between religion-based discriminative trust and religiosity is strongest among Muslims and Hindus (Table 21). Meanwhile, the link between ethnicity-based discriminative

[18]On the other hand, Table 3 suggests that the distribution of responses to the religiosity question between different religions are rather similar except for Hindus, whose distribution appears to be slightly skewed to the right, suggesting that the perception of what religiosity means may not be so different between religions.

trust and religiosity is weakest among Buddhists (at 10% significant) and Protestants.

The results on tolerance confirm our findings from the previous analysis on inter-religion differences. As shown in Tables 22 and 23, for the most part, the negative link between religiosity and tolerance is present only among Muslims. That link is, to a much lesser extent, also present among Protestants, but interestingly, only for the issues that religious believers find least contentious – i.e., allowing non-coreligionists to live in the village or neighborhood. Meanwhile, a comparison between the two Christian religions suggest that the link between tolerance and religiosity is more positive for Catholics compared to Protestants in all tolerance measures.

I also use a similar strategy to examine whether having a coreligion education affect cooperative attitudes differently across different religions.[19] As shown before, having a coreligion education is positively correlated with discriminative trust towards coethnics and coreligionists, and less overall tolerance. Unlike adherents of the other religions, however, Catholics seem to defy this pattern: Catholics who receive a Catholic education is more likely to be more trusting of strangers and more tolerant in allowing non-coreligionists build their house of worship. However, at the same time, they are also more intolerant towards having non-coreligionists live in the village or neighborhood – although these coefficients are only significant at 10%. Meanwhile, Buddhists who receive a Buddhist education tend to be less trusting in the community – they are more cautious of their neighbors, and are less willing to entrust neighbors to watch their children or home.

4.4 Diversity and cooperative attitudes

We next examine how religious diversity – measured using fractionalization and polarization measures – is correlated with cooperative attitudes. Alesina and La Ferrara (2002) found that diversity was negatively correlated with trust, which they argued, because individuals like to interact with people who are similar to them. On the flip side, diversity means a higher likelihood of contacts with those who are different from us, and frequent contacts may break down stereotypes, increase trust, and reduce prejudice (Allport, 1954; Uslaner, 2010).

Tables 24 to 25 present the estimation results of the district fixed-effects model for trust and tolerance. Both diversity measures are not associated with any changes in the nondiscriminative trust variables. However, as

[19] Among the categories of religious institutions that manage private schools in IFLS, there is no school managed by a Hindu-based institution.

shown in Table 26, both fractionalization and polarization are negatively associated with discriminative tolerance with regards to ethnicity and positively correlated with all measures of tolerance. In addition, the magnitude of coefficients are largest for the three most contentious issues that are captured by the tolerance measures. This piece of evidence, in particular the coefficient on the polarization measure, suggests that inter-religion interactions do not translate into inter-religion competition. Instead, it provides support for the contact hypothesis. However, since we cannot rule out the issue of endogeneity (e.g., through residential sorting), a better identification strategy may be necessary to establish causality.

4.5 Cooperative attitudes by gender

The next question is whether the coefficients of our model differ by gender and, in the next section, by the different age groups. For both analyses, I consider the community fixed-effects model used above to analysis the link between religiosity and cooperative attitudes. To begin, I perform tests for pooling male and female respondents across all outcome indicators. The results, which are not reported, suggest that except for three variables (i.e., trust of neighbors, tolerance with respect to allowing non-coreligionists to live in the neighborhood and to build their house of worship), we can reject that all of the coefficients are the same between male and female.[20]

Tables 27 to 32 present the results. Overall, the link between religiosity and attitudes is stronger for men than women. The extent to which individuals are more willing to entrust their house or children to their neighbors as they are more religious is larger among men than women. Similarly, the link between trust (both the non-discriminative and discriminative variants, see Tables 29 and 30) and religiosity is also stronger among men. Similarly, the extent to which men become more intolerant as they become more religious is larger compared to that of women. If we were to take a causal interpretation, then one can interpret this as suggesting that religious commitment alters cooperative attitudes more among men than women.

Meanwhile, the gender differences in the impact of having received coreligion education are much smaller. The main gender differences are mostly with respect to tolerance indicators. The negative correlations between coreligion education and tolerance are stronger among women for tolerance in allowing non-coreligionists live in the village or in the house, and in allowing

[20]The critical value for rejection is at 1% except for tolerance in allowing non-coreligionists in the village and in the house, which are rejected at 5%.

non-coreligionists build a house of worship. However, it is weaker for women with respect to tolerating inter-faith marriage.

4.6 Cooperative attitudes by age groups

To analyze how the coefficients differ by age groups, I categorize the sample into four age groups: Under 25 years old, between 25 and 45 years old, between 45 and 65 years old, and more than 65 years old. Like before, I then perform the tests for pooling across age groups under the community fixed effects specification that I used to analyze the link between religiosity and attitude. The hypothesis that the sample can be pooled is rejected at 10% for local altruism norm, at 5% for discriminative trust and tolerating non-coreligionists in the neighborhood, and at 1% for the assessment of village safety at night, trust of the police, and tolerating non-coreligionists in the village. The pooling hypothesis cannot be rejected for the remaining outcome variables. In the following analysis, we will only look at the breakdowns for altruism norm, trust of the police, discriminative trust, and tolerance for non-coreligionists in the village and neighborhood.

There does not appear to be a monotonic relationship between strength of the link between cooperative attitudes and religiosity as one gets older. As shown in Table 33, the link between religiosity and altruism is weakest during the early productive years, and is strongest in the old age. The link between religiosity and trust of the police is weakest at the very young age, and strongest when old. Again, here, the relationship is not monotonic, as trust slightly declines in late middle age.

Meanwhile, the strengths of the links between religiosity and religion-based and ethnic-based discriminative trusts appear to peak at late middle-age, but falter in the old age (Table 34). However, Table 35 indicates that in the case of tolerance, the negative links between religiosity and tolerance with regards to allowing non-coreligionists in the village or neighborhood were strongest among those in the youngest age group. Similar to the case with discriminative trust, the link between religiosity and tolerance tends to falter and disappear among the oldest age group.

Unlike those between religiosity and cooperative attitudes, the strengths of the relationships between coreligion education and cooperative attitudes – in particular, the discriminative kind – appear to be monotonic in age. The magnitudes of the positive links between coreligion education and discriminative trusts, and the negative links between coreligion education and tolerance tend to fall for older age groups. In fact for the two tolerance measures, those in the oldest group who received coreligion education in their

youths are more tolerant than those who do not.

4.7 Social desirability and interviewer effects

One of the findings from social psychology studies on religion is that there exists a positive link between individual religiosity and social desirability bias (Batson et al., 1993; Trimble, 1997). To wit, more religious people are more likely to answer in a way that make them look favorable to others. In this case, the one obvious "others" whom respondents might want to look favorable to is the interviewer.

As a preliminary attempt to address this potential bias, I use the interviewer codes that are available in the IFLS dataset for each individual to re-estimate the model to include the interviewer fixed effects. I focus on the link between religiosity and cooperative attitudes. If interviewer effects did bias the responses of the more religious, the inclusion of the interviewer fixed effects will reduce the magnitude of the point estimates for attitudes that are generally accepted as "good behavior" (such as altruism and non-discriminative trust) and increase those that tend to be thought of as "bad behavior" (such as intolerance). On the hand, the bias on discriminative trust, may differ depending on the interviewer's characteristics, such as whether the respondents believed that their particular interviewer is a coreligionist.

As shown in Tables 36 to 38, the joint tests on the interviewer fixed effects suggest that the interviewer effects are present across all outcome variables. Meanwhile, Hausman tests indicate that for most outcomes, the differences between the religiosity coefficients under the model with the interviewer fixed effects and those without are not statistically significant.[21] Based on the Hausman tests, the differences in the religiosity coefficients for the two models are different for the following outcomes: Caution, the willingness to trust neighbors to watch one's house, general assessment of village safety, trust of neighbors and the police, and tolerance in allowing non-coreligionists live in one's house.

In all cases where the differences are deemed significant based on the Hausman tests, the magnitudes of the religiosity coefficients are smaller in the interviewer fixed-effects model. There is not a single case where the fixed effects change the sign of the coefficients, and among those whose differences

[21] Following Wooldridge (2002, p.291), I use a robust form of the Hausman test by conducting a Wald test (with the variance clustered at the interviewer level) on whether the coefficient on the interviewer-mean of the religiosity variable on the pooled OLS regression is significant.

are deemed significant, there is only a single case where the inclusion of the interviewer fixed effects remove the statistical significance. These results on the interviewer effects are still preliminary, and at present, I am working on examining how different interviewer characteristics may affect the different coefficients.

5 Conclusion

The analysis provides evidence on the positive association between religion and in-group trust. Across religions, more religious people tend to trust neighbors and members of their communities more. In-group trust, however, is not accompanied by out-group trust: there is no correlation between religiosity and trust towards strangers. Trust towards strangers is typically understood to be the correct measure of social or civic capital, as it allows cooperation across individuals from different groups (Glaeser et al., 2000; Guiso et al., 2011). Religiosity is also associated with more ethnic- and religion-based discriminative trust and more trust of the authority.

There are inter-religion differences in oooperative attitudes. Community trust is lowest among Protestants and, to some extent, Buddhists. Meanwhile, non-discriminative trust do not seem to vary by religion. However, discriminative trust and religious tolerance do vary by religion. Muslims and Hindus tend to exhibit more ethno-religious discriminative trust. Muslims are also the most intolerant among the adherents of the various religions, while Buddhists and Catholics are among the most tolerant. Meanwhile, when their religion is the majority, Protestants are most willing to helpful their neighbors. Meanwhile, when their religion is the majority in the village, Muslims tend to be the least tolerant compared to Protestants and Hindus.

We find a similar pattern when we examine the strength of the associations between religiosity and adherence to the different religions. The association between religiosity and community trust is, as before, weakest among Protestants and it is strongest among Hindus. With respect to discriminative trust, the associations between religiosity and ethno-religious biases are again strongest among Muslims and Hindus. Furthermore, the association of between religiosity and tolerance is only negative among Muslims and – in a much lesser extent – Protestants. These negative associations were present across all tolerance measures for Muslims, while for Protestants, they are only present on the two least contentious issues measured by the tolerance indicators.

In terms of how social interactions affect trust and tolerance, I find some support for the contact hypothesis. Having received a non-coreligion education is associated with less discriminative trust and greater tolerance in most of the measures here. Moreover, village-level diversity is positively associated with tolerance – although this last evidence must be interpreted with caution, given the potential of selection bias due to residential sorting.

I also find that among the Christian religions, Indonesian Catholics tend to be more trusting and tolerant than Protestants. This is contrary to what might be expected if we look at the aggregate-level evidence which documented a link between lower trust and Catholicism (e.g., La Porta et al., 1997) which, it was argued, might be due to the tendency of Catholicism to breed hierarchical and not horizontal trust (Putnam et al., 1993). Guiso et al. (2003) argued that this signaled a change in Catholicism and, using cross-country evidence, provided evidence that it had become more tolerant following the Second Vatican Council. At the same time, it might also reflect how history has shaped both Catholicism and Protestantism in Indonesia.

These findings are suggestive of the link between religion and parochial altruism in Indonesia. This link is present in all religions, as evidenced by the links between religiosity and community trust and discriminative trust and altruism, but not between religiosity and generalized trust. However, the manifestation of parochial altruism appears to be strongest for the religion that is the majority in Indonesia, namely Islam: We only find consistent negative relationships between religiosity and tolerance among Muslims.

These results provide a clue for understanding the link between religion and development. In many developing countries, politicians often resort to religion as a means to garner support. Indonesia is a case in point. The fall of the secular, authoritarian, and centralized government in 1998 has allowed a more important role for religion in the public space. Moreover, decentralization without a clear political commitment to separate the state and the church/mosque has allowed regions to implement policies with distinctly religious flavor (Bush, 2008).[22] As suggested here, this greater political space for religion can potentially exacerbate existing tensions between adherents of different religions. Following the suggestions of Guiso et al. (2006), the relevant follow-up question, then, is to examine the causal links from these attitudes to economic outcomes, particularly those that depend on inter-group cooperation.

[22] As of 2008, Bush (2008) counted 78 district regulations in 52 districts/municipalities that are religion-based.
